Seismological Aspects of the 1976 Eruptions of Augustine Volcano, Alaska

By John W. Reeder and John C. Lahr

Abstract

Data from seismograph stations operated by the U.S. Geological Survey and the National Oceanic and Atmospheric Administration Palmer Observatory around Cook Inlet, Alaska, have proved useful in studying various aspects of the 1976 Augustine volcano eruptions that commenced on January 22. Shallow earthquakes, volcanic tremor, and eruption-induced air-phase disturbances all accompanied the Augustine 1976 eruptive activity. These related seismic events, including their seismic time sequences, revealed information on (a) the source mechanisms of the eruptions, (b) the earthquake frequency-to-magnitude relationships, (c) the relationships between shallow earthquakes and volcanic tremor, (d) the eruption-induced air-phase mechanism, and (e) the seismic-geologic relationships.

The first eruption of Augustine volcano in 1976 began at about 18:00 on January 22. This pyroclastic eruption commenced with no obvious seismic warning except for some minor shallow-earthquake activity that had occurred since May 1975. This eruption was followed by a very large swarm of shallow earthquakes with local magnitudes of 2.5 or less. The swarm reached a peak of 90 recognizable earthquakes per hour and lasted for 13.5 h. A series of 12 large vent-clearing pyroclastic eruptions followed. In general, each eruption generated a gradually increasing and then gradually decreasing seismic signal at the closest station, which was 82 km from Augustine volcano. Such signals, observed at distances of up to 321 km, are believed to result directly from tremor that was caused by the transport of gases, magma, and (or) rock through the volcano.

Disturbances following seven of the last eight large January eruptions and traveling about 0.3 km/s were recorded by seismograph stations to the northeast at distances of up to 321 km. These signals are interpreted as atmospheric pressure disturbances that were generated by northeast-directed explosions from the volcano and that were then transmitted by favorable atmospheric conditions. This interpretation is supported by the destruction during the January eruptions of the northeast part of the crater wall. These blasts were carried across the total length of Cook Inlet and were best recorded at seismograph stations not topographically shielded from Augustine volcano and situated on glacial deposits.

The next series of eruptions, which began on February 6, was smaller and occurred over eight days during the final part of the vent-clearing stage and then during the principal part of the dome-building stage of the volcano. This series was accompanied but not preceded by increased seismic activity. The final eruptive activity, which commenced on April 13 and lasted about six days, was less explosive and appeared to be associated with minor dome growth. No eruption-induced air-phase disturbances were detected for any of the February or April eruptions.

INTRODUCTION

Augustine volcano, an andesitic calc-alkaline volcano located in the Cook Inlet of south-central Alaska, erupted explosively on January 22, 1976. This volcanic activity, consisting mainly of a series of explosive vent-clearing pyroclastic eruptions that were accompanied by shallow-earthquake swarms, lasted four days. Explosive eruptions began again on February 6, and these eruptions were also accompanied by shallow earthquake swarms and lasted eight days. This second phase of eruptive activity was initially vent clearing, but the later eruptions of this phase were definitely associated with the extrusion of a new lava dome (Johnston, 1978). The final eruptions, which were less explosive and appeared to be associated with minor dome growth, commenced on April 13 and lasted about six days. Augustine volcano has also erupted in 1883, 1935, 1963/64, and most recently in 1986 (Kienle and others, 1986). These other eruptions were also principally pyroclastic eruptions.

Seismic stations operated by the regional National Oceanic and Atmospheric Administration (NOAA) and the U.S. Geological Survey (USGS) recorded the 1976 eruptive activity of Augustine volcano. In order to gain insight into the nature of this volcanic activity, seismograms from stations that recorded the eruptions were analyzed.

Acknowledgments.—Special thanks are extended to J.L. Stith, L.F. Radke, D.A. Johnston, D.J. Lallà, and Juergen Kienle, who, through their own research...
efforts, have given valuable insight into the 1976 volcanic activity of Augustine volcano. Thanks are also given to George Thompson, FW. Klein, and Elliot Endo, who provided very helpful and constructive reviews of this report, and to C.H. Cramer, who helped with the initial identification of the air-phase seismic signals.

SEISMIC DOCUMENTATION

The 1976 eruptions of Augustine volcano were recorded by the Cook Inlet segment of a regional USGS and NOAA seismograph network. The stations in the Cook Inlet region are shown in figure 1. Two of the USGS stations, CKK and BIG, which are located 82 km northwest and 103 km west, respectively, of Augustine volcano, recorded the eruptive activity. The USGS seismograph stations NNL, ILM, RDT, NKA, and SKL, which are located 142 km, 97 km, 146 km, 197 km, and 221 km, respectively, from Augustine volcano, recorded only the larger events. The NOAA seismograph stations KDC and PWA, which are located 185 km south-southeast and 321 km northeast, respectively, of Augustine volcano, also recorded some of the larger volcanic activity. All of these stations were functional throughout the eruptions despite adverse weather conditions and the remoteness of the region.

The University of Alaska local seismograph network, consisting of five stations on Augustine Island and three stations near Augustine Island on the mainland, went out of operation before the main January eruptive activity. Two of the Augustine Island stations failed on December 4 and 26, respectively, and the other stations on the island failed on January 2, possibly due to mudflow activity (Kienle and Forbes, 1976) or to bad weather and electronic malfunctions (Johnston, 1978). Nevertheless, the University of Alaska seismograph network, originally established on Augustine Island in 1970, has documented earthquake activity prior to the 1976 eruptions (Mauck and Kienle, 1973; Lalla and Kienle, 1978; D. J. Lalla, oral and written commun., 1978; Lalla and Kienle, 1986). A new seismograph network was installed by the University of Alaska in time to record the April 13-18 volcanic activity. Although the University of Alaska data are being analyzed and published separately, some of the results from their efforts have been used to help interpret the regional USGS and NOAA network recordings of the Augustine eruptive activity.

Data from the USGS and NOAA seismograph stations were telemetered to a central recording point, the NOAA Palmer Observatory. The standard equipment for each USGS station included a vertical seismometer with a natural frequency of 1.0 Hz (Mark Products, Model L4), an amplifier, and a voltage-controlled oscillator (USGS, Model J-202). The recording facility, operated by the NOAA Alaska Tsunami Warning Center, utilized a bank of discriminators (Develco, Model 6203), a 16-mm film multichannel oscillographs (Geotech, Model 4000D), a time-code generator (Datatron, Model 3150-209-1), and a radio receiver for WWV time signals (Specific Products, Model SR7R). The multichannel oscillograph photographically recorded 18 different seismic channels along with time marks on a single roll of film. This film was then analyzed by means of a Geotech Model 6585 film viewer. Time was based on universal time (U.T.) for the entire seismograph network. The response characteristics of the entire seismic system from seismometer to film viewer have been described by Lahr and others (1974).

TYPES OF SEISMIC SIGNALS

Seismic activity in volcanic regions has been classified according to the nature of the seismic signal and to the relationship of such signals to volcanic eruptions. A standard classification discussed by Shimozuru (1971) and Minakami (1974) recognizes:

(1) A-type earthquakes. These have shallow focal depths of between 1 and 10 km, occur within 20 km of the volcanic vent, and show distinct P and S phases.

(2) B-type earthquakes. These have focal depths of less than 1 km, are concentrated immediately beneath the eruptive crater, and do not show clear P or S phases.

(3) Explosion earthquakes. These have no clear P or S phases and are associated with explosive activity.

(4) Volcanic tremor. These are similar to B-type or explosion earthquakes, except that they are of long duration and are interpreted being related to subsurface volcanic magma and (or) gas transport (Aki and Koyanagi, 1981). Such signals can last several minutes to continuous periods of time (Shimozuru and others, 1966; Kubotera, 1974; Koyanagi, 1982).
A modified version of this well-known classification scheme was proposed by Latter (1981). In Latter's scheme, the term "volcano–tectonic earthquake" was proposed, which includes all earthquakes in the vicinity of a volcano that have the high–frequency appearance of the A–type earthquakes of Shimoizuru and Minakami but are not necessarily greater than 1 km in depth. Latter also used the term "volcanic earthquakes," which includes B–type and explosion earthquakes as well as earthquakes that have the low–frequency appearance of B–type earthquakes but occur at depths greater than 1 km.

Seismogram recordings are influenced by the sensing instrument, the hypocenter distance, the nature of the Earth's crust between the hypocenter and the seismograph stations, and the source mechanism. Unfortunately, in the case of the 1976 Augustine eruptions, the hypocenter distances to the recording stations were large, the nature of the Earth's crust between the hypocenter and the seismograph stations is still poorly understood, and the source mechanism for all practical purposes is still unknown. These factors make it difficult to apply the standard classifications, such as those discussed above, to the Augustine eruptions. A more simplified scheme was therefore used.

The USGS and NOAA seismograph stations recorded the following recognized types of seismic signals during the Augustine eruptions:

1. Shallow earthquakes. These have fairly sharp onsets with well-defined phases, a frequency range of 3 to 10 Hz (with the dominant frequency being 4-6 Hz), and hypocenters not more than 40 km from Augustine volcano (normally within 20 km of Augustine volcano). This type of earthquake would be similar to Latter's volcano–tectonic earthquakes.

2. Volcanic tremor. These have emergent onsets, have poorly defined phases where pulsating signals are not unusual, and have a frequency range of 0.4 to 8 Hz (with the dominant frequency being 2-7 Hz and the average frequency 4.5-5 Hz). These signals can have a short duration like those of shallow earthquakes, and they would include Latter's volcanic earthquakes. They can also be of longer duration, where they would include Shimoizuru and Minakami's and (or) Latter's volcanic tremor.

3. Eruption–induced air–phase signals. These have emergent onsets, an overall equal rate of growth and decay (although pulsating signals are not unusual), a frequency range of 1 to 12 Hz, and a velocity of about 0.3 km/s.

shallow Earthquakes

The USGS seismograph stations CKK and BIG were used for determining the number and magnitude of Augustine Island shallow earthquakes because the more distant seismograph stations were not as sensitive in detecting this activity. The time–interval range between P and S arrivals at CKK and the time–interval range between P arrivals at CKK and BIG were established from a review of the large earthquake swarm at Augustine Island of January 22 and 23, 1976, which preceded the main January eruption sequence. The P arrival time at BIG was found to range from 2.8 to 3.8 s after the CKK P arrival time, and the S minus P arrival–time interval at CKK was found to range from 10.0 to 12.0 s. Because hundreds of these earthquakes were recorded during the beginning of the eruption, a fair degree of confidence was established in recognizing Augustine events as based on this criteria. These P and S arrival–time differences were used for the rest of the record as the criteria for determining whether or not recorded earthquakes were related to Augustine volcano.

A seismogram of a typical Augustine earthquake of December 21, 1975, is shown in figure 2. This particular event had a S minus P arrival–time interval of 11.3 s at CKK. The P arrival at BIG was 3.3 s later than the P arrival at CKK. The frequency of the P wave at CKK was about 5 Hz, and the maximum peak–to–peak amplitude was 18.4 mm. Based on the work of Doug Lalla at the University of Alaska (Lalla and Kienle, 1978; D.J. Lalla, oral and written commun., 1978), the hypocenter of this event was determined to lie beneath the summit of Augustine volcano at a depth of 0.6 km below sea level. Lalla's detailed results, which covered the October through December 1975 pre-eruption period, show that all of the earthquakes that fit the arrival–time requirements established for BIG and CKK and that had a P–wave frequency of about 5 Hz at CKK occurred near the summit of Augustine volcano at depths no greater than 1.1 km below sea level. A few earthquakes were detected that satisfied the Augustine arrival–time criteria on CKK and BIG and that had CKK frequencies higher than 5 Hz. Lalla found that the hypocenters of such earthquakes were similar to shallow (that is, less than 1.1 km below sea level) and were located in the southeast region of the volcano.

During the February eruptions, numerous earthquakes were detected at CKK and BIG that deviated from the typical Augustine events. These earthquakes had a P–phase frequency usually as high as 10 Hz and an S minus P arrival–time interval at CKK of about 9.8 s. At first, it was believed that they were not Augustine events. Similar events, such as the two shown in figure 3, were also recognized by Lalla during the pre-eruption period of 1975. The event of December 29, 1975 (fig. 3A) was found by Lalla to have a hypocenter 3.8 km below sea level and 3 km northwest of the summit. This event had an S minus P arrival–time interval at CKK of 9.76 s, a frequency of about 9 Hz, an unusually large S–phase arrival, and a local magnitude $M_L$, as based on equation (2) below, of 2.2. The event of November 21, 1975 (fig. 3B), was found by Lalla to have a hypocenter 7.2 km below sea level and beneath the summit. This event had an S minus P arrival–time interval at CKK of 9.6 s, a frequency of about 9 Hz, and an $M_L$ of 1.6. Based on pre-emption data from the University of Alaska seisograph network, Lalla found that the hypocenters of such events were located under Augustine Island at depths ranging from 1.4 to 16.4 km below sea level. Based on some of Lalla's more accurately located pre-eruption shallow earthquakes, a plot was constructed of the S minus P arrival–time intervals at CKK with respect to calculated depths (fig. 4).
For this paper, the Augustine shallow earthquakes with $S$ minus $P$ arrival-time intervals of between 10.0 and 12.0 s (that is, probable hypocenter depths less than 1.1 km below sea level) are referred to as very shallow earthquakes. The Augustine earthquakes having $S$ minus $P$ arrival-time intervals of between 9.4 and 10.0 s (that is, probable hypocenter depths greater than 1.1 km but less than 20 km) are referred to as moderately shallow earthquakes. Both categories of earthquakes are shallow earthquakes (that is, earthquakes having hypocenters of up to 20 km below sea level).

The Richter's local magnitude for these shallow earthquakes was calculated using the following formula (Lahr, 1980):

$$M_L = \log_{10} \left( \frac{A}{2C} \right) - B_1 + B_2 \log_{10} (D^2) - R_{kd},$$

where

$A =$ maximum peak-to-peak earthquake amplitude in millimeters;

$D =$ distance in kilometers from the epicenter to the seismic station;

$R_{kd} =$ normality correction factor.

Figure 2. Seismogram of a typical Augustine shallow earthquake with $M_L = 1.6$ as recorded at seismic stations NNL, CKK, and BIG on December 21, 1975. Hours, minutes, and seconds (12:00:30) given in universal time (u.t.).

Figure 3. Seismograms of two moderately shallow Augustine earthquakes. A, Earthquake of December 29, 1975 ($M_L = 2.2$). B, Earthquake of November 21, 1975 ($M_L = 1.6$). Seismic stations denoted at left.
C = peak-to-peak amplitude in millimeters for a
10 \mu V \text{rms (root mean square), 5-Hz test}
voltage introduced at preamplifier input;

B_1 = 0.15, for 1 km \leq D \leq 200 km;
B_2 = 0.80, for 1 km \leq D \leq 200 km;

D = \sqrt{X^2 + Z^2}, where X is the epicentral distance
(about 82 km for CKK), and Z is the focal depth in kilometers;

\text{and}

R_{tf} = \text{frequency response of system for frequency } f.

Equation (1) reduces to

\begin{equation}
M_L = \log_{10} \left( \frac{A}{18.0} \right) + 2.9 - 1.3
\end{equation}

where Z is assumed to be zero, R_{tf} is equal to 1.3 at a
frequency of 5 Hz, and C equals D_1 and
written commun., 1978). Based on equation (2), the

\begin{equation}
\text{calculated } M_L \text{ value for the December 21, 1975,
Augustine earthquake is } 1.6.
\end{equation}

The earthquake-radiated energy E (in ergs) for
these shallow earthquakes was calculated using the
following empirical relationship (Richter, 1958):

\begin{equation}
\log_{10} E = 9.9 + 1.9 M_L - 0.024 M_L^2.
\end{equation}

Based on equation (3), the calculated radiated energy for the
December 21, 1975, Augustine earthquake is
about 7.8 \times 10^{12} \text{ ergs.}

The larger Augustine shallow earthquakes were
located using the HYPOELIPSE computer program as
described by Lahr (1980). Initially, the P-wave
horizontally layered velocity model developed by
Matumoto and Page (1969) for the eastern Kenai
Peninsula and the Prince William Sound region was
considered for locating these earthquakes. Seismic

refraction work by Pearson and Kienle (1978)
suggested a cylindrical model for Augustine that consisted of a 2.25-2.6 km/s core flanked by
pyroclastic material having velocities as low as 1.2
km/s. A velocity of 2.7 km/s was determined by
Pearson and Kienle immediately beneath the volcano
to a depth of about 09 km below sea level. The
Matumoto and Page regional model is a poor
representation of the shallow velocity structure of
the Augustine volcano region. For this reason, the model
was abandoned and a horizontally layered model
developed by the University of Alaska (J. Kienle, oral.
commun., 1977) was adopted with modification (table 1).
A value of 1.78 for the ratio between P and S
velocity was assumed for the entire model.

The P-velocity data base, this model represents the best horizontally layered model for the
Augustine volcano region. Although any model that is
described by uniform horizontal layers is a poor
representation of the actual velocity structure of the
immediate Augustine volcano region (Mitronovas and
Isacks, 1971; Lahr, 1975; Pearson and Kienle, 1978),
such models do have the advantage of simplifying the
computation of travel times. It was found by using
HYPOELIPSE and the above model that the
hypocenter locations for the main earthquake swarm
of January were fairly scattered, with most events
located northwest of Augustine Island and at depths as
great as 60 km.

To better locate Augustine events with the
horizontally layered crustal model given in table 1,
station P-wave delays were assigned by using a well-
located earthquake event as a master event. The pre-
eruption Augustine shock of 08;51 November 19, 1975,
which was located by the University of Alaska
seismograph network, was chosen as the master event.
Station delays of +0.13 s, +0.36 s, +0.38 s, +1.04
s, +0.37 s, +1.36 s, +0.10 s, and +0.39 s were assigned
to CKK, BIG, ILM, NNL, RDT, NKA, SKL, and SPU,
respectively, in order to reduce the P-phase residuals
for this master event to zero.

The horizontal P-velocity model (table 1), with
incorporated station delays, was used with the
HYPOELIPSE computer program to calculate
hypocenter locations for the Augustine earthquake
events. The calculated hypocenters for the January,
February, and April eruption periods are shown in
figure 5. The calculated hypocenter locations for the
February events were less scattered than those for the
January events. This is because three of the
University of Alaska seismograph stations on the
mainland (that is, OPT, CDA, and MNC) were included
in determining the February hypocenter locations. The
April earthquake hypocenter determinations, which
also included readings from one of the University of
Alaska seismograph stations located on Augustine
Island, showed the least amount of scatter.

The northwest trend in the epicenter locations
for the January eruptive period was originally thought
to correspond to the principal horizontal tectonic
stress orientation, which should be about N. 30, W. for
Augustine Island (Nakamura and others, 1977). Because of the poor quality of the epicenter data, a
statistical approach was undertaken for a typical very
shallow earthquake where the arrival times at every
station were allowed to vary randomly with a standard

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure4.png}
\caption{S minus P arrival-time intervals at seismic station CKK versus calculated hypocenter depths for some of the larger 1975-76 pre-emption shallow Augustine earthquakes (D.J. Lalla, written commun., 1978).}
\end{figure}
deviation of 0.16 s. A 21:26 January 22, 1976, earthquake was chosen for this test, and the results also reveal a northwest orientation in the scatter of these locations (fig. 6). Random errors in reading the arrival times combined with the geographical distribution of the seismograph stations probably caused the observed northwest-trending scatter of earthquake epicenters.

Because the hypocenter locations for the January through April Augustine earthquakes could not be satisfactorily determined, the criteria based on frequency and relative P and S arrival times at CKK were used to recognize Augustine events and to determine their approximate hypocenter depths.

Volcanic Tremor

During the 1976 eruptions of Augustine volcano, many signals were recorded that do not have the appearance of shallow earthquakes (that is, Latter’s volcano-tectonic earthquakes). These signals have emergent onsets, reach maximum amplitudes usually before the halfway mark of their total duration, and can have longer durations than shallow earthquakes. A high degree of variation exists among these signals, but for classification purposes in this paper they are divided into two groups: small-amplitude and large-amplitude volcanic tremor, or more simply small and large tremor. The large tremors recorded at CKK were defined to have peak-to-peak amplitudes of over 2 cm as measured on a Geotech Model 6585 film viewer, while the small tremors were defined to have peak-to-peak amplitudes on CKK of less than 2 cm. At the beginning of this study, it was not known if these signals correlated with eruptive events.

Dibble (1974) described "vibrations," that accompanied eruptions of Ruapehu volcano in New Zealand. These "vibrations" accompanied eruptions of mud and ash, occurred often with little warning, had durations usually of 1 min, and had roughly equal rates of growth and decay. Larger "vibrations," which accompanied injection of vesicular andesite in the

Figure 5. Hypocenters for some of the larger 1976 very shallow earthquakes of Augustine volcano. A. Earthquake swarm of January 22-25. B. Earthquake swarm of February 6-14. C. Earthquake swarm of April 13-18.
Crater Lake of Ruapehu volcano, reached maximum amplitudes in about 18 s, had emergent onsets, and decayed slowly for over 3 min. The small and large Augustine volcanic tremors appear to be similar to Dibble's "vibrations," and yet they have some different characteristics. Like Dibble's small "vibrations," the Augustine small tremors are emergent and most have nearly equal rates of growth and decay. However, some of the Augustine small tremors lasted much longer than 1 min. Most of these were found to have a somewhat pulsating amplitude with time, a pattern that deviates from that of equal rates of growth and decay. Most of the Augustine large tremors have emergent onsets similar to Dibble's large "vibrations," but differ in that they usually display a symmetrical growth and decay rate with some amplitude fluctuations superimposed (figs. 21, 23).

Large Tremor (Large-Amplitude Volcanic Tremor)

At about 18:00 on January 22, 1976, a large pyroclastic eruption occurred at Augustine volcano. This eruption was confirmed by infrasonic signals and ash falls (Kienle and Shaw, 1979). The corresponding signal recorded at CKK (fig. 7) had an emergent onset and built rapidly to a maximum amplitude in about 14 s. This signal decayed over a period of 3.75 min and is similar to a signal recorded by a Willmore vertical station 9.1 km from Ruapehu volcano for a steam eruption at that volcano on July 24, 1966 (Dibble, 1974). Originally the Augustine signal was not recognized as representing a major eruptive event because such a rapid rise to maximum amplitude was not typical of the other Augustine eruptive signals (that is, large-amplitude volcanic tremor). The rapid increase in amplitude is now interpreted as being the P-phase arrivals of several very shallow Augustine earthquakes in close succession where each earthquake was larger than the preceding one. At least three very shallow earthquakes are believed to be represented, and the largest of these earthquakes had an approximate local magnitude of 2.3. The P-phase arrivals of these earthquakes are marked by arrows in figure 7. These earthquake arrivals would have helped obscure the emergent onset of the principal eruptive signal.

The large tremor of 18:00 January 22 is not typical of most Augustine large tremors, which usually have less rapid amplitude growths and thus have more symmetrical signals. For example, the large tremor of 13:55 January 23, 1976 (figs. 8, 21C), started as a small tremor at 13:45:22, reached a 2-cm peak-to-peak amplitude at about 13:53:25, peaked at about 13:54:45, and finally ended at about 14:05:00. This particular large tremor had a total duration of 18.5 min. Thirteen large tremors were recorded during the January eruptive activity, and three more were recorded during February. All of these in detail had unique amplitude configurations (figs. 21, 23).

All 16 of the Augustine large tremors (figs. 21, 23) have been verified as representing or at least roughly correlating with major eruptive events as indicated by infrasonics (Kienle and Shaw, 1979), by direct observation of some of the eruptions (Kienle and Forbes, 1976; Trapp, 1976; Hobbs and others, 1977; Stith and others, 1978), and by NOAA-4 satellite photographs. One such satellite photograph, taken on January 23, 1976, at 20:05:07, shows several eruptive clouds from events that occurred during the preceding several hours (fig. 9). Other evidence for eruptions included observations of ash falls, damage to flying aircraft by ash clouds, lidar detection, and radar detection of ash clouds (Kienle and Shaw, 1979; Remsberg and others, 1976; Johnston, 1978). In table

Types of Seismic Signals
2, the times of the large tremors recorded at CKK are given along with the infrasonic evidence for the times of major eruptive events at Augustine volcano.

Small Tremor (Small-Amplitude Volcanic Tremor)

Small tremors are, as previously defined, emergent Augustine signals at CKK with peak-to-peak amplitudes of less than 2 cm. Hundreds of small tremors were recorded during the Augustine eruptive period. Although most of these small tremors were under 2 min in duration, the longest had a duration of over 40 min. The typical small tremor of 11:23 January 23 (fig. 10) started at about 11:22:14, peaked at about 11:23:20, and ended at about 11:24:00. Although this signal was in general fairly symmetrical, it did pulsate markedly.

A tremor that lasted at least 25 min and had a large enough amplitude at CKK to be classified as a large tremor for about 4 min occurred on February 9. A seismogram for part of this tremor is shown in figure 11, along with a photograph by Jeff Stith of the University of Washington Cloud and Aerosol Physics Group of the Atmospheric Science Department that shows the eruptive activity of the volcano at 00:04. Unfortunately, the period from 23:59 February 8 to 00:03 February 9 was not seismically recorded as a result of a film change. Therefore, the pyroclastic flow shown in figure 11C was not seismically recorded. The pulsating nature of small-tremor signals can be easily seen in figure 11A. Such signals might have resulted from shallow-earthquake swarms at the summit region of the volcano, where the signals have been highly attenuated as a result of the physical nature of the volcanic pile.

![Seismogram of a January 23, 1976, Augustine eruption (large tremor). Seismic stations denoted at left.](image-url)
Occasionally, very shallow Augustine earthquakes appear to be related to small tremor. For example, the $M_T \geq 1.8$ earthquake at 23:35:11.5 on February 13 was followed by a small tremor and an eruptive cloud (fig. 12), as documented by the University of Washington Cloud and Aerosol Physics Group (L.F. Radke and J.L. Stith, oral commun., 1976). This suggests a relationship of very shallow earthquakes to eruptive events and tremor.

Some Correlations and Correlation Problems Between Observed Eruptive Activity and Volcanic Tremor

Between February 8 and February 19, 1976, 10 airborne visits to Augustine volcano were made by the University of Washington Cloud and Aerosol Physics Group (Stith and others, 1978). Numerous eruptive clouds were observed by this group during their visits. For example, a photograph, which was taken during their approach to Augustine volcano on February 8-9, documented two large eruptive clouds (fig. 13A) that appear to correlate with a 22:27:02 large tremor and a 22:53:44 small tremor. When the University of Washington group arrived at Augustine volcano, they observed signs of a very recent pyroclastic flow (fig. 13B), which probably corresponds to the 22:27:02 large tremor. The small cloud above the volcano probably corresponds to the detected tremor of 23:35:49. Based on automatic photographs taken during the University of Washington visits to Augustine, 11 eruptive clouds were observed. All eruptive clouds observed by the University of Washington group correlate with tremors. The only tremor for which the group did not

Figure 9. Satellite photograph of Alaska taken at 20:05:07 u.t. on January 23, 1976, by NOAA-4. Circle on photograph indicates location of Augustine volcano.
observe an eruptive cloud occurred at 00:10:21 on February 10. The failure to observe an eruptive cloud for this tremor might have been due to the poor weather conditions.

Even though the correlation between the observed eruptive clouds and large tremor is good, such a correlation does not necessarily mean that all eruptive signals (that is, small- and large-amplitude volcanic tremors) recorded during the 1976 Augustine eruption period correlate directly with respect to time with actual eruptions. For example, a period of about 8 min was described by the University of Washington Cloud and Aerosol Physics Group as the duration of the main eruption shown in figure 11, which started at about 00:00:00 February 9. An examination of figure 23C shows that small tremor was actually recorded from 00:00:03 to 00:28:00, and that a large tremor actually occurred between 00:10:00 and 00:13:47. As previously mentioned, the period from 23:58 February 8 to 00:03 February 9 was not seismically recorded as a result of a film change. Because of the size of this eruption (fig. 11), a large tremor is suspected to have occurred during this film change. Yet, the 3.78 min of the large tremor that started at 00:10:00 actually occurred after the main eruption was reported by the University of Washington group. A careful examination of photographs of this period indicates the continuous emission of ash "steam" clouds, which were not in the amount expected for the amplitude of the large tremor or of the small tremor recorded at CKK. This 00:10:00 large tremor was the only recorded large tremor that does not correlate directly with respect to time with a large explosive eruption of Augustine volcano.

Another observation of eruptive activity by the University of Washington Cloud and Aerosol Physics Group is shown in figure 14. During this activity, base surges blanketed at least the upper one third of Augustine volcano, with at least one pyroclastic flow reaching halfway down the volcano (fig. 14). The seismic signal, which corresponded to this eruptive activity, started as a small tremor at about 00:30:49.5 February 13, 1976, and was followed by a shallow earthquake at 00:30:50.8. Although the photograph is timed at 00:34:00 and indicates continued movement of the pyroclastic flow, the actual seismic signal preceded it by several minutes. Photographic evidence suggests that the pyroclastic flow was in progress as early as 00:32:30 and that downslope movement had already stopped by 00:41:20. The seismic signal preceded the pyroclastic flow and may have preceded the start of the summit eruption.

Most likely, considerable eruptive activity occurred at Augustine Island that was not recorded by the CKK and BIG seismograph stations. A vertical view of the summit and northeast flank of Augustine volcano is shown in figure 15. This NASA photograph was taken at 03:22 on April 13, 1976. At this time, shallow-earthquake swarms with no tremor were being recorded by the CKK seismograph station. The photograph indicates eruptive activity by the dark clouds of ash and steam at the summit and by

10 Seismological Aspects of the 1976 Eruptions of Augustine Volcano, Alaska
cloud trails from the paths of recent small pyroclastic flows that had gone through the northeastern crater breach of the volcano.

**Eruption-Induced Air-Phase** signals

During part of the January 1976 eruptive period, very pronounced disturbances, which followed a good number of the major eruptions, were recorded by seismograph stations in the Cook Inlet region. One-minute windows of the seismogram that recorded such a disturbance along with the preceding 11:22:00 January 24, 1976, are shown in figure 16. The NNL seismograph station initially detected the disturbance, which had a frequency range of 1.0 to 12 Hz and a maximum amplitude of 3.6 cm. NKA then recorded the disturbance, with a frequency range of 1.0 to 9 Hz and a maximum amplitude of 12.0 cm, followed by SKL with a frequency range of 1.0 to 9 Hz and a maximum amplitude of 2.1 cm. The disturbance was then recorded about 321 km northeast of Augustine volcano by the PWA seismograph station; the signal recorded there had a frequency range of 2.1 to 4.0 Hz and a maximum amplitude of 7.6 cm.

These seismic disturbances are similar to large-amplitude volcanic tremor because they have indistinct first arrivals and, in general, equal rates of growth and decay. The seismic disturbances were pronounced enough to be originally used instead of the large tremors on CKK to recognize major eruptive events. The disturbances, except for those on PWA, were confined between 20:09:43 January 23 and 15:25:00 January 25 and have velocities of about 0.33 km/s, based on a correlation with the corresponding large tremors. The relationship of the duration of these signals to the duration of the corresponding large tremors and to the time from the start of these corresponding large tremors is illustrated in figure 17.

The speeds of these disturbances are approximately the same as the 0.313 km/s speed for lower-channel infrasonic waves from the Trident and Redoubt explosive eruptions that were detected by microbarometers (Wilson and Forbes, 1969), which is approximately the speed of sound at this latitude in winter (Diamond, 1963). The speed of sound for motionless air can be approximated (Hardy and others, 1942) by the following relation:

\[ c = 20.1 \sqrt{T}, \]

where

- \( C \) is the speed of sound measured in meters per second; and
- \( T \) is temperature in Kelvins.

The approximate temperature of the first kilometer of atmosphere in the Cook Inlet region on January 24, 1976 (fig. 29B), was -10°C (263 OK). At such a temperature, the speed of sound as given by equation (4) would be about 0.326 km/s. These disturbances appear to be atmospheric pressure disturbances that were generated by eruptions of Augustine volcano. Such signals are henceforth called eruption-induced air-phase signals.

![Seismogram of January 23,1976, Augustine eruption (small tremor).](image-url)
The complete sequence of Augustine events as detected by the seismograph station CKK is shown in figure 18 for the time period from November 1, 1975, to April 30, 1976. Included in this summary are (A) the daily count of very shallow Augustine earthquakes (<1.1 km below sea level as based on the criteria for P and S arrival times at CKK and BIG); (B) the daily count of very shallow earthquakes for the period of November through December 1975 as based on University of Alaska seismic data (D.J. Lalla, oral and written

Figure 11. Seismogram and photographs related to February 8-9, 1976, eruptive activity of Augustine volcano. A, Seismogram of small tremor, which is part of long tremor of February 8-9. B, Photograph of 00:04:00 u.t. February 9 showing corresponding eruptive activity. C, Photograph of 00:02:40 u.t. February 9. Photographs taken by the University of Washington Cloud and Aerosol Physics Group.
commun., 1978); (C) the daily count of moderately shallow Augustine earthquakes (≤1.1 km but <20 km below sea level as based on the criteria for relative P and S arrival times and frequencies at CKK and BIG); (D) the daily count of small tremor recorded by the CKK seismograph station; (E) the daily total duration in minutes of small tremor; (F) the daily count of large tremor recorded by the CKK seismograph station; and (G) the daily total duration in minutes of large tremor.

A good part of the smaller seismic activity probably would have been missed by the CKK and BIG seismograph stations, since these stations are located 82 and 103 km, respectively, from the summit of Augustine Island. Of the 452 very shallow earthquakes detected during November and December 1975 by the University of Alaska seismograph network, only 176 were detected by the CKK and BIG seismograph stations (figs. 18A, B). Based on equations (2) and (3), the total radiated energy from all shallow Augustine earthquakes detected by CKK during this period was $1.2 \times 10^{15}$ ergs (fig. 19). This compares to about $1.9 \times 10^{15}$ ergs as detected by the University of Alaska seismograph network. Even though the CKK and BIG seismograph stations failed to detect some of the smaller Augustine seismic activity, the data from these stations were selected for examination because they were the closest continuously operating stations during the 1976 Augustine eruptions.

Extensive precursor activity in the form of shallow earthquakes occurred before the onset of the initial eruption of Augustine volcano on January 22, 1976 (fig. 18). Such activity began as early as May 1975 (Kienle and Shaw, 1979; Lalla and Kienle, 1978). The largest precursor swarm occurred on November 18–19, 1975, and consisted of 90 very shallow earthquakes. These earthquakes had a total of 0.65 $\times 10^{15}$ ergs of radiated energy. The largest event of the swarm had a local magnitude of about 2.3. Very shallow precursor earthquake swarms also occurred on December 1–2, 13–14, 21–22, 24, 26–29, and December 31–January 2.

Of special interest are the moderately shallow earthquakes. Such events occurred on November 12, 21, 26, December 2, 28, 29, January 4, 15–18, and 21 (fig. 18). The January 15–18 swarm, the largest moderately shallow precursor swarm before the January 22 eruption, consisted of nine earthquakes. These earthquakes had a total of 0.13 $\times 10^{15}$ ergs of radiated energy and had $M_r$ values of up to 2.0. The moderately shallow event of January 21, which had a local magnitude of 1.7, occurred just 24.66 h before the first Augustine explosive eruption of 17:59:29.9 January 22. No moderately shallow Augustine events were detected during the January or April eruptive periods, but such events were fairly common during the February eruptions. In fact, the February earthquake swarms consisted of 43 moderately shallow earthquakes. This was the largest concentration of moderately shallow earthquakes to occur between November 1975 and April 1976.

A total of 1,064 very shallow earthquakes

![Figure 11. Continued.](image)
accompanied the eruptive activity that began on January 22. These earthquakes radiated a total of $31.0 \times 10^{12}$ ergs of energy. During this eruptive period, 13 major eruptive events (that is, large tremors) and at least 22 smaller eruptive events (that is, small tremors) occurred as based on the seismic record (table 2). Very few earthquakes occurred in the 11 days following this first eruptive sequence.

---

14 Seismological Aspects of the 1976 Eruptions of Augustine Volcano, Alaska
Eruptive activity commenced again on February 6. A total of 321 very shallow and 43 moderately shallow earthquakes, which collectively represented a total of $0.94 \times 10^{13}$ ergs of radiated earthquake energy, occurred during this second eruptive period. This eruptive period included 3 major eruptive events (large tremors) and at least 125 smaller eruptive events (small tremors) as based on the seismic record.

The third eruptive sequence commenced on April 13 after 53 days of few earthquakes. Initially, this eruptive sequence was represented by a very shallow

Seismic Time Sequence 15
earthquake swarm and with possible seismically undetected small eruptions. This swarm ended on April 14, but very shallow earthquake swarming and numerous small tremors occurred again during April 16-18. Forty-five small eruptive events (small tremors) were detected during the period of April 16 through 18. Between April 13 and 18, a total of 81 very shallow earthquakes occurred, which represented approximately $0.076 \times 10^{15}$ ergs of radiated energy.

**The January Eruptive Sequence**

The January eruptive sequence is summarized in figure 20. This summary on an hourly basis includes (A) the count of very shallow earthquakes; (B) the count of small tremor; (C) the total duration in minutes of small tremor; (D) the count of large tremor; and (E) the total duration in minutes of large tremor.

The eruptive sequence began with no obvious warning at approximately $17:59:42$ on January 22 as a large tremor (figs. 7, 21A). This eruptive event might have started as early as $17:59:29.9$ as a very weak small tremor. As previously described, this seismic signal had an emergent onset and built rapidly to a $17:59:45$ maximum peak. Three very shallow Augustine earthquakes occurred in close succession during this rapid build up, at $17:59:41.4$, $17:59:42.3$, and $17:59:43.2$. Their local magnitudes are estimated to be at least 1.6, greater than 1.6 but less than 2.3, and 2.3, respectively. Very shallow Augustine earthquakes also occurred during the eruption, at $18:02:19.8$ and $18:02:46.6$ with $M_L = 1.5$ and $M_L = 1.7$, respectively. The only very shallow Augustine earthquakes to occur within the 72 h preceding this eruption were an $M_L = 0.64$ earthquake at $17:39:51$, an $M_L = 0.82$ earthquake at $04:16:24$, and an $M_L = 1.5$ earthquake at $02:55:48.5$. Two moderately shallow

![Figure 15. A vertical photograph of summit and northeast flank of Augustine volcano taken by NASA at 03:22 u.t. on April 13, 1976.](image)
events occurred during the preceding 72 h. These were an $M_L = 1.6$ earthquake at 17:19:06.5 on January 21 and an $M_L = 0.64$ earthquake at 07:00:31 on January 20.

Following the initial large tremor, an $M_L = 1.2$ earthquake occurred at 18:32:25.6 (fig. 21A), which marked the onset of the largest of the shallow-earthquake swarms (fig. 20A). Initially the earthquakes in this swarm, all being very shallow, occurred at a rate of about 43 events per hour. By 03:00 on January 23, the earthquake rate reached its peak of 90 recognizable events per hour. The largest earthquake occurred at 21:16:01 January 23 with an $M_L$ of 2.5. By 07:00 the rate had dropped to 33 events per hour, and for all practical purposes the swarm ended at 08:08:43. During this swarm period, over 667 earthquakes occurred and about $27 \times 10^9$ ergs of earthquake energy was radiated. This 13.5-h

peak of the large tremor but not into the second. This may indicate that the two peaks represent two overlapping large tremors. A somewhat different pattern is shown for the large tremors of 17:41 January 23, 18:40 January 24, and 14:57 January 25 (fig. 21G, M, N), since they were preceded by only one or two earthquakes. Again, no earthquakes occurred during or after these large tremors.

Earthquakes occurred before, during, and after the large tremors of 20:09 January 23 and 05:59 January 24 (fig. 21H, J). This deviation from the sequence described above suggests that some of these shallow earthquakes might have occurred independently of the 20:09 and 05:59 large tremors.

Eruption-induced air-phase disturbances were detected northeast of Augustine volcano in the Cook Inlet region during the January eruptions by seismograph stations. The arrival times and durations of the air-phase seismic signals for the January large tremors have been listed in table 3 for the NNL, NKA, SKL, and PWA seismograph stations. In addition, the maximum peak-to-peak amplitudes of signals at PWA are given. PWA recorded these disturbances for every large-tremor event during the January eruptive period except for those of 17:50 January 22 and 16:10 January 23. These air-phase signals were confined between 20:09 January 23 and 15:25 January 25 at NNL, between 02:21 January 24 and 15:25 January 25 at NKA, and between 02:21 January 24 and 19:02 January 24 at SKL. The reason for the air-phase time confinement is probably due to the nature of the eruptions and (or) to atmospheric conditions.

![Figure 19](image)

The February Eruptive Sequence

The February eruptive sequence is summarized in figure 22. This summary on an hourly basis includes (A) the count of very shallow earthquakes, (B) the count of moderately shallow earthquakes, (C) the count of small tremor, (D) the total duration in minutes of small tremor, (E) the count of large tremor, and (F) the total duration in minutes of large tremor.

Without obvious warning the February eruptive sequence began at about 14:44:14 on February 6 as small tremor, increased to large tremor, and then decayed with a fairly symmetrical distribution of amplitudes over time (fig. 23A). Two other large tremors have been recognized during this February eruptive period. One started at about 22:27:02 February 8 and the other at about 00:10 February 9.

Unlike most of the January large tremors, the February ones were not preceded by very shallow earthquake swarms. In fact, these large tremors appear to have little relationship to the Augustine shallow earthquakes.

The February eruptive sequence consisted of numerous very shallow earthquake swarms, moderately shallow earthquake swarms, and small tremors. A total of 321 very shallow Augustine earthquakes occurred. These were fairly evenly distributed over the eruptive period. A total of 43 moderately shallow earthquakes occurred of which 32 were between 6:00 February 7 and 10:00 February 9. In contrast, 231 of the 255 February small tremors occurred between 13:00 February 8 and 9:00 February 14.

Many of the February small tremors appear to correspond to some of the very shallow earthquakes. In some cases small tremors may have been "triggered" by shallow earthquakes, as indicated in figure 12, where a 23:35:11.5 February 13 earthquake immediately preceded small tremor and an observed eruptive cloud.

The energy radiated by the moderately shallow earthquakes during the February eruptions was about $0.26 \times 10^{19}$ ergs as based on equation (3). This is about 46 percent of the total energy radiated between November 1, 1975, and April 30, 1976, by all of the moderately shallow Augustine earthquakes. Most of the rest (52 percent) of the radiated energy from moderately shallow earthquakes occurred during the 15 days prior to the initial January 22 eruption.

The April Eruptive Sequence

The April seismic eruptive sequence is shown in figure 24. This summary on an hourly basis includes (A) the count of very shallow earthquakes, (B) the count of small tremor, and (C) the total duration in minutes of small tremor. No moderately shallow earthquakes and no large tremors were detected during this period of eruption.

The April eruptive sequence consisted of 81 very shallow earthquakes. This sequence also included 45 small tremors, ranging from 0.40 to 2.10 min in duration with an average duration of 0.94 min. This eruptive sequence began with an earthquake swarm at 00:25:23 on April 13. The swarm consisted of 29 very shallow Augustine earthquakes, which lasted until 09:56 on April 14. Following 42 hours of quiescence, a second phase of the April eruptive sequence began at 04:14 on April 16 as a series of small tremors. Shallow earthquake swarming did not occur until 07:28 on April 16.

SEISMIC DATA INTERPRETATIONS

Source Mechanisms for the Eruptions

One of the major problems in seismology is understanding the source mechanisms of seismic signals from volcanoes. With respect to volcanic tremor, similar signals have been generated by pyroclastic flows, lava avalanches (Shimozuru and others, 1969), rockfalls (Tilling and others, 1975), and geysers (Rinehart, 1965; Kieffer and Ihlen, 1977). It is believed that explosive seismic signals are caused by the vibration of a spherical magma chamber (Kobotera, 1974) or of a cylindrical chamber and (or) conduit (Shimozuru, 1961; St. Lawrence and Qamar, 1979). It has been argued that such vibrations are due to magma movements, due to the "implosion of vapor bubbles" (Kieffer and Ihlen, 1977), and due to the transition from subsonic speeds to supersonic speeds of

---

Figure 20. Sequence of Augustine events between 00:00 u.t. January 22 and 12:00 u.t. January 26, 1976.
moving gases (Steinberg and Steinberg, 1975) that were possibly caused by the “sudden release of pressure in the gas by the mechanical failure of a capping retaining medium” (Self and others, 1979). Explosive seismic signals might also be caused by vibration of a magma-filled crack that is being extended by magmatic pressure, or by vibration of a chain of cracks separated by barriers that yield to magma pressures in a "jerkily" fashion (Aki and others, 1977).

Because of the large distances between Augustine volcano and the seismograph stations and because of the complex crust of this region, the volcanic tremor may have been caused by shallow-earthquake (that is, Latter's volcano-tectonic earthquake) swarms in the summit region of Augustine, where the seismic signals have been highly attenuated. Such attenuated signals have been observed by MacDonald and Eaton (1964, their fig. 36) in Hawaii for shallow earthquakes recorded at distances greater than 15 km from their epicenters. In addition, if the shallow earthquakes occurred at a very high rate, the earthquake signals would overlap and possibly result in the volcanic tremor that was observed. For example, Malone and Qamar (1984) observed signals during the 1984 eruptions of Mount St. Helens that graded from distinct earthquakes to volcanic tremor and then back to distinct earthquakes. Malone and Qamar interpreted this volcanic tremor as at least partially due to a high frequency of similar-sized earthquakes. The Augustine earthquake swarms could be related to the mechanical failure of the retaining medium" in the

![Figure 21](image-url)

**Figure 21.** Augustine peak-to-peak amplitudes (A), in centimeters, & large tremor and local magnitudes (ML) of very shallow earthquakes during January 22-25,1976. Amplitudes were recorded at seismic station CKK.
conduit. If this interpretation is correct, not all tremor necessarily corresponds to eruptions. However, the direct observations during some of the February eruptions do suggest such a one-to-one correspondence.

**Earthquake Frequency-to-Magnitude Relationships**

The frequency distribution of magnitudes of the Augustine shallow earthquakes is shown in figure 25. Both the interval distribution (the number of events within the interval \( M_L \) to \( M_L + 0.05 \)) and the cumulative distribution (the number of events greater than or equal to \( M_L \)) are shown for the following groups of events: (A) the January 22-23 main earthquake swarm; (B) the January 23-25 eruptive period; (C) the February 5-16 eruptive period, excluding events more than 1.1 km below sea level (that is, the moderately shallow earthquakes); (D) the April 13-20 eruptive period; (E) the December 21, 1975, to January 3, 1976, period, excluding the moderately shallow earthquakes; and (F) the November 1, 1975, to April 30, 1976, period of moderately shallow earthquakes. Each of the cumulative distribution plots may be fitted by two straight-line segments having the form (Gutenberg and Richter, 1949)

\[
\log_{10} N = a - b M_L
\]

where \( N \) is the total number of earthquakes having a magnitude greater than or equal to \( M_L \).

The parameters \( a \) and \( b \) satisfying equation (5) for each of the cumulative distribution plots have been determined by fitting straight-line segments by eye and are given in figure 25. Parallel lines have also been fitted by eye to the interval distribution data.

At initial glance, the lines may appear to fit the cumulative distributions fairly well. Unfortunately, many of the groups of events are small, resulting in substantial uncertainty in the estimated parameters. The scatter of the data is shown most clearly in the cumulative distributions fairly well. Unfortunately, variations in the distributions must be used with caution.

Nevertheless, despite these complications, some very interesting frequency-to-magnitude relationships exist. For example, the earthquake frequency per 0.05-ML interval for the January 22-23 main earthquake swarm (fig. 25B) ranges from about 24 earthquakes at $M_L = 0.8$ to about 15 earthquakes at $M_L = 1.7$. The frequency of earthquakes over this $M_L$ range is nearly constant. Then, at $M_L = 1.75$, the frequency jumps up to 21 earthquakes per 0.05 $M_L$.

Figure 22. Sequence of Augustine events between 12:00 u.t. February 6 and 13:00 u.t. February 14,1976.

24 Seismological Aspects of the 1976 Eruptions of Augustine Volcano, Alaska
This frequency also stays nearly constant until $M_L = 1.95$. A large frequency jump occurs at this point, with the rate becoming as high as 52 earthquakes per 0.05 $M_L$, and then the frequency decreases rapidly. This second frequency jump at $M_L = 1.95$ corresponds with the intersection of the two line fits to the cumulative distribution. Although no other $M_L = 1.95$ earthquake frequency jumps have been recognized in the rest of the data, $M_L = 1.75$ jumps appear to occur for the January 23-25 eruptive sequence and for the February 5-16 sequence (fig. 25B, C). For January 23-25, the frequency jumps at $M_L = 1.95$ from an expected 7 earthquakes per 0.05 $M_L$ to 14 earthquakes per 0.05 $M_L$. For February 5-16, the frequency jumps at $M_L = 1.75$ from an expected 3 earthquakes per 0.05 $M_L$ to 6 earthquakes per 0.05 $M_L$. In addition, an earthquake frequency jump from an expected 3.5 earthquakes per 0.05 $M_L$ to 8 earthquakes per 0.05 $M_L$ occurs at $M_L = 1.4$ for the December 21-January 3 earthquake swarm. Upon close examination of the February 5-16 earthquake swarm, an increased earthquake frequency jump also occurs at $M_L = 1.4$.

The breaks of slope in figure 25 are believed to be real because the detection threshold of the operating network was about $M_L = 0.8$ to $M_L = 1.0$. Also, such breaks have been observed elsewhere for A-type and B-type volcanic earthquakes (Filson and others, 1973; Guerra and others, 1976; Tanaka, 1967), as well as for fracture experiments performed in the laboratory (Mogi, 1962; Scholz, 1968; Warren and Latham, 1970). The high $b$ values (as high as 6.0) observed for Augustine volcano are comparable to the high $b$ values determined for A-type and B-type volcanic earthquakes elsewhere (Suzuki, 1959; Shimozuru, 1971).

The jump increase in the earthquake frequency at some upper $M_L$ value, and the break in the slope of the line fit to the interval and cumulative earthquake frequency distributions, might reflect an upper size restriction for faulting due to some physical and (or) chemical boundary condition in the crust. For example, the size of the largest earthquakes may be restricted to the dimensions of one very large cell or chamber. Such a large cell might contain most of the
hypocenters for the smaller earthquakes. It was found from seismic observations by Filson and others (1973) of a volcanic eruption in the Galapagos Islands that the caldera collapse of a cylindrical plug resulted in an increased b value in the cumulative earthquake distribution for a surface wave magnitude (\(M_s\)) greater than 4.5. This may have resulted from the finite dimensions of the collapse, which did not produce any earthquakes larger than \(M_s = 5.1\). At Augustine volcano, the dimensions of the active conduit and (or) active magma body might have restricted the size of the larger earthquakes. In fact, the dimensions of the active conduit and (or) active magma body might have even concentrated the occurrences of the larger earthquakes to some upper \(M_L\) value. This might explain the existence of the Augustine earthquake frequency jumps.

Another change in the cumulative distributions with time was the position of the "knee," the magnitude above which the cumulative distribution steepens (fig. 25). The knee is located at about \(M_L = 1.95\) for January 22-23 and January 23-25, and at \(M_L = 1.8\) for February 5-16. For April 13-20, the knee is estimated to be about \(M_L = 1.1\). This change appears to correlate with the earthquake frequency jumps as well. The movement of both the knee and the highest \(M_L\) earthquake frequency jump to smaller magnitudes with respect to time could reflect a reduction in the dimensions of the region of high stress, which would also reflect a reduction in the dimensions of the seismically active conduit and (or) active magma system. In fact, the position of the knee and of the earthquake frequency jump (\(M_L = 1.1\)) for the April 13-20 period is so small that it probably reflects a restriction of the eruptive activity to just the immediate summit region.

In addition, the variation in the b values with time for the smaller earthquakes can be partially understood by considering the arguments presented by Warren and Latham (1970). In laboratory experiments...
in which samples were subjected to thermal gradients, Warren and Latham found relatively high b-values, from 1.2 to 2.7, which they attributed to the nonuniformity of the thermally induced stress. They noted that tension fractures growing into high-stress regions will tend to propagate orthogonally into other cracks, resulting in a cellular crack pattern. As time continues, the cellular fracture pattern would become finer, and a larger proportion of small earthquakes would occur, increasing the b value. It can be speculated that the increase of the b value with time for the smaller shallow Augustine earthquakes (January 22–23, 0.2; January 23–25, 0.8; February 5–15, 1.4; and April 13–20, 1.3) might be due to a decrease in the size of the cellular fracture pattern in the upper part of a magma chamber and its immediate surroundings—that is, the volcanic conduit and (or) magma body region down to a depth of 1.1 km below sea level.

Correlations Between Shallow Earthquakes and Explosive Activity

Correlations of deep (>40 km) and (or) large (>5.5 Ms) earthquakes with volcanic activity have been found (Yamashina and Nakamura, 1978; Carr and Stoiber, 1973; Latter, 1971; Tilling and others, 1976; Yokoyama, 1971; Eaton, 1962). Shallow–earthquake swarms have been documented as occurring before and during eruptive activity in the Hawaiian Islands (Eaton, 1962), in the Mediterranean (Guerra and others, 1976), in the Galapagos Islands (Filson and others, 1973), and in the Orient (Minakami, 1960, 1974; Shimozuru, 1971). Shallow–earthquake events and swarms have been observed to precede the January eruptions and to occur during February eruptions of Augustine volcano.

Because very shallow earthquake swarms immediately preceded (by up to 0.5 h) and possibly relate to most of the large tremors occurring during January (fig. 21) and because very shallow earthquake swarms occur during tremors in February, the earthquake–radiated energy sequence was compared with the small- and large–tremor sequence by means of crosscorrelation statistical techniques (Davis, 1973). In this correlation technique, a temporal sequence of radiated energy sequence is compared with itself (autocorrelation) or with another temporal sequence of events (crosscorrelation). This is done by linear correlation between the earthquake energy sequence and the same sequence at later intervals of time (autocorrelation) or between the earthquake energy sequence and another time sequence at later intervals of time (crosscorrelation). This simple statistical investigation was undertaken to determine if there was any statistical support for the observed correlations.

Such a comparison is shown for the 08:30 January 23 through 03:30 January 24 eruptive period in figure 26, where very shallow (less than 1.1 km below sea level) earthquake radiated energy and small- and large–tremor duration were determined for 15-min intervals. The 15-min interval was selected because very shallow earthquake swarms appeared to occur within 15 min of the large January volcanic tremors. Although the correlation is not as good as originally suspected, the comparison does suggest that very shallow earthquakes, which precede eruption events, correlate with such events and that the peak of radiated energy from such swarms usually precede the seismic peak of the eruption by about 15 to 30 min (fig. 26A).

For the February 7 through February 14 eruptive period, similar correlation comparisons were undertaken for very shallow earthquake radiated energy and the duration of small and large tremor (fig. 27A, D), for moderately shallow earthquake radiated energy and the duration of small and large tremor (fig. 27E, F), and for moderately shallow earthquake radiated energy and very shallow earthquake radiated energy (fig. 27G, H). There appears to be a direct correlation between very shallow earthquake radiated energy and small- and large–tremor duration, which confirms the observed increase in earthquake activity during tremors. But no obvious correlation for moderately shallow activity with very shallow activity or with eruptive activity was found (fig. 27E–H). Possibly the time–lag delay observed for the January eruptions with respect to shallow earthquakes was due to obstructions in the upper part of the conduit. Such obstructions were then cleared by the time of the February eruptions.

A similar correlation comparison was made for the April eruptive period, and no correlations were found between very shallow earthquakes and small tremors (fig. 28). This suggests, as previously indicated by the earthquake b values, that the dimensions of the conduit had been reduced. It is possible that the conduit was no longer transporting magma, and thus the source of the small April eruptions could have been from the immediate summit region.

![Figure 26. Correlations between radiated energy of very shallow earthquakes and volcanic tremor duration between 08:30 u.t. January 23 and 03:30 u.t. January 24, 1976.](Image)
The Air-Phase Mechanism

Eruption-induced air-phase signals from Augustine volcano were detected by seismograph stations located northeast of Augustine Island to distances of up to 321 km (figs. 16, 17; table 3). Air-phase disturbances were noted in 1955 at distances of 65 km northeast of Bezymianny volcano during its eruption (Gorshkov, 1959), and seismometers near other erupting volcanoes have detected atmospheric pressure disturbances coupling to the ground (Yoshidome and Seino, 1968; Minakami, 1974; Nairn and others, 1978). More recently, air-wave disturbances from the 1980 eruption of Mount St. Helens have been detected by seismograph stations to distances of 11,300 km (Donn and Balachandran, 1981; Sawada and others, 1982). Such air-to-ground coupling has been documented for meteors (Donn and Balachandran, 1974; Nagasawa, 1978), for large unidentified bodies from space (most likely large meteors) that have hit the Earth (Ben-Menahem, 1975), and for aircraft sonic booms (McDonald and Goforth, 1969). Conversely, ground disturbances due to earthquakes have coupled to the atmosphere, resulting in sound disturbances (Hill and others, 1976). During the 1883 Krakatoa eruption, some air-phase disturbances coupled to the ocean surface (Harkrider and Press, 1967).

It is not completely understood why air-phase disturbances occurred in the Cook Inlet region during the period between 14:13 January 23 to 15:25 January 25 (table 3). As previously mentioned, seismic recordings are influenced by the type of sensing instrument, the hypocenter distance, the nature of the energy-transporting media between the hypocenter and the sensing instrument, and the source mechanism. All of the seismograph stations detecting the air-phase

---

**Figure 27.** Correlations between very shallow Augustine earthquake radiated energy, moderately shallow Augustine earthquake radiated energy, and Augustine volcanic tremor duration between 00:00 u.t. February 7 and 00:00 u.t. February 14, 1976.

**Figure 28.** Correlations between very shallow Augustine earthquake radiated energy and Augustine small-tremor duration between 08:00 April 16 and 16:00 April 18, 1976.
disturbances except SKL were located on unconsolidated deposits, which is a medium better suited than bedrock for air-to-ground seismic coupling. The only factors that might have influenced the air phase with respect to time would have been the atmospheric conditions (energy-transporting media) and the explosive mechanism at the volcano (source mechanism).

During the January 23-25 period of the air-phase eruptive detections in the Cook Inlet region, the atmospheric conditions were favorable for transmitting air-phase disturbances from Augustine Island up the Cook Inlet. As described by Pridmore-Brown (1962), air-disturbance rays from a source are bent "downwards on the downwind side," and such downward bending is accentuated by positive temperature gradients (inversions). For the first 0.5 km of the atmosphere during this time, the wind shifted from being a northeast wind (blowing toward the southwest) to a west wind, to a southwest wind, and then finally to a south wind (National Weather Service; fig. 29). Temperature inversions also occurred (fig. 29).

A crater formed during the January eruptions, and by the end of this first eruptive period it had a depth of 200 m. It was breached sometime during the January eruptions on its northern side. More extensive pyroclastic flow deposits were found on the northern flank of the mountain than elsewhere (Johnston, 1978). Such deposits probably resulted from several directed blasts from the crater break. North- or northeast-directed blasts at the summit of the volcano could have triggered the atmospheric pressure disturbances, which then traveled northeast up the Cook Inlet during the January 23-25 eruptions.

**Seismic-Geologic Correlation**

Although the limited amount of direct observations indicate a correlation of small and large tremors with volcanic eruptions, the relationship of tremors to the stratigraphy of the 1976 eruption deposits is not obvious. For example, Johnston (1978) reported the following deposits for the January eruptive period (bottom to top): (a) a discontinuous tan ash; (b) a gray ash present nearly everywhere, which possibly represented two distinct deposit layers; (c) an olive ash layer in the northeastern quadrant of the island; (d) three pumiceous pyroclastic flow deposits; and (e) pyroclastic flow deposits on all flanks of the mountain. The relationship of these observed deposits to the 13 detected large tremors and the 22 small tremors can only be speculated. Considering the number of seismic eruptive events, it is suspected that other erupted horizons might be found, especially on the upper slopes of the volcano.

Johnston (1978) reported for the February and April eruptions two fairly large pyroclastic flow deposits on all flanks of the volcano, and then about 70 to 100 smaller pyroclastic flow deposits on the northeast flank of the volcano. Possibly the two initial pyroclastic deposits correspond to the first large tremor and the following small–tremor cluster of 14:45 on February 6 and of 02:17 to 04:38 on February 7, respectively. The other 70-100 smaller pyroclastic flow deposits might correspond to the other 116 small tremors and the other 2 large tremors of February (fig. 22) and to the 45 small tremors of April (fig. 24). Perhaps not all of the February and April small tremors represented eruptions. It is more likely, however, that not all of the erupted horizons have been found or that some of the horizons were possibly destroyed by overriding pyroclastic flows.

A dome began to grow sometime between February 6 and 12 within in crater of Augustine volcano and continued to grow during the rest of the February and April eruptions (Johnston, 1978). It is suspected, partly as a result of the blocky nature of most of the pyroclastic flow deposits, that most of the tremors were related to eruptions associated with the growth of this new dome, whereas most of the tremors observed during the 08:00 to 13:45 eruptive period on

---

**Figure 29.** Radio soundings of the atmosphere at Kodiak (triangles), King Salmon (squares), and Anchorage (circles), (NOAA, National Weather Service). Wind azimuths are given just for Anchorage. January 23 were related to eruptions occurring while the old 1963–64 dome still existed. This old dome probably was destroyed by the large tremor of 13:46 January 23.

In order to account for the plagioclase microphenocryst observed in the erupted deposits, Johnston (1978) concluded that roughly 13 to 80 days of mixing of basalt and dacite at a depth of about 2–10 km would have been required before the first eruption. Interestingly enough, this time period roughly correlates with the time span of the moderately shallow earthquakes that occurred before the January eruptions at depths between 1.1 and 20 km below sea level. (These earthquakes preceded the January eruptions by up to 71 days, as shown in figure 18C–E.)

CONCLUSIONS

Shallow earthquakes, volcanic tremor, and eruption-induced air-phase signals were recognized as seismic signals related to the Augustine 1976 eruptive activity. These seismic events, including their seismic time sequence, revealed information about (a) the source mechanisms of the eruptions, (b) the earthquake frequency-to-magnitude relationships, (c) the relationships between shallow earthquakes and volcanic tremor, (d) the eruption-induced air-phase mechanism, and (e) the seismic-geologic relationships.

The volcanic tremor in general appears as gradually increasing and then decreasing seismic signals, which in detail actually pulsate. These signals are believed to possibly result from tremor caused by the transport of gases, magma, and (or) rock through the conduit during volcanic eruptions. Because of the large distances between Augustine volcano and the seismograph stations and because of the complex crustal structure at the volcano, the tremors might have also been caused by highly attenuated earthquake swarms consisting of a high frequency of similar-sized events in the summit region of the volcano. Such swarms could be related to the mechanical failure of any retaining medium in the conduit region and could account for the pulsating nature of the tremor signals.

The frequency distribution of magnitudes for Augustine shallow earthquakes varies with respect to both time and earthquake size, and it appears to reflect different stages and aspects of the volcanic eruptive process. Even though a fair amount of scatter exists in the magnitude distribution data, these data have been roughly fitted by two straight-line segments, each having the form of the Gutenberg and Richter (1949) relationship. In these frequency-to-magnitude plots, the line segment for the larger earthquakes is always the steeper of the two. This larger slope for larger earthquake magnitudes is believed to be caused by the restriction of the size of the largest earthquakes to the boundaries of the Augustine shallow magma body and (or) conduit. The steepening of the slope for the smaller shallow earthquakes with time during the 1976 eruptive period might be due to the decrease in size of the cellular fracture pattern in the upper part of the Augustine magma body and (or) conduit region.

Although the first January eruption began with no obvious warning, shallow-earthquake swarms preceded by up to 30 min many of the January eruptions; in contrast, during February, swarms occurred during but did not precede the eruptions. It is suspected that the time-lag delay observed for the January eruptions with respect to shallow-earthquake swarms was due to obstructions in the upper part of the conduit that were cleared by the time of the February eruptions. No correlation appears to exist between shallow earthquakes and small tremor for the April eruptive period. Such a lack of correlation suggests that the conduit between the magma at depth and the summit of the volcano was no longer transporting gases, magma, and (or) rock.

During the period of the air-phase eruptive disturbances in the Cook Inlet region (14:13 January 23 to 15:25 January 25), the atmospheric conditions were favorable for transmitting such disturbances up Cook Inlet. Not only did temperature inversions exist during at least part of this time, but the winds were also out of the southwest for part of this time period. In addition, north- to northeast-directed eruptive blasts were believed to have occurred, which would have been ideal for triggering any northeastward-traveling atmospheric pressure disturbances.

Although the limited observations of Augustine eruptions indicate a correlation between seismic tremor and volcanic eruptions, the relationship between tremor and the stratigraphy of the 1976 erupted deposits is not obvious. Considering the number of tremors, it is suspected that more 1976 erupted horizons might still be found on Augustine Island.
